# The genetic basis and fitness consequences of sperm midpiece size in deer mice

Heidi S. Fisher<sup>1,†</sup>, Emily Jacobs-Palmer<sup>1</sup>, Jean-Marc Lassance<sup>1</sup> & Hopi E. Hoekstra<sup>1</sup>

An extensive array of reproductive traits varies among species, yet the genetic mechanisms that enable divergence, often over short evolutionary timescales, remain elusive. Here we examine two sister-species of *Peromyscus* mice with divergent mating systems. We find that the promiscuous species produces sperm with longer midpiece than the monogamous species, and midpiece size correlates positively with competitive ability and swimming performance. Using forward genetics, we identify a gene associated with midpiece length: *Prkar1a*, which encodes the R1 $\alpha$  regulatory subunit of PKA. R1 $\alpha$  localizes to midpiece in *Peromyscus* and is differentially expressed in mature sperm of the two species yet is similarly abundant in the testis. We also show that genetic variation at this locus accurately predicts male reproductive success. Our findings suggest that rapid evolution of reproductive traits can occur through cell type-specific changes to ubiquitously expressed genes and have an important effect on fitness.

The remarkable diversity of male reproductive traits observed in nature is often attributed to the evolutionary forces of sexual conflict, sperm competition and sperm precedence<sup>1–4</sup>. However, the genetic mechanisms that enable reproductive traits to respond to changes in selective regime are often unknown. Moreover, because most genes expressed in reproductive organs (for example, testis) are also expressed elsewhere in the body<sup>5,6</sup>, genetic changes that result in reproductive trait modification can potentially lead to negative pleiotropic consequences in either the opposite sex or in other tissues. Despite these constraints, reproductive phenotypes show striking and often rapid divergence, and can promote speciation<sup>7</sup>.

Two closely related *Peromyscus* rodents with highly divergent mating systems show marked variation in male reproductive traits<sup>8–11</sup>. Within the genus, the deer mouse, *P. maniculatus*, is considered one of the most promiscuous species: both sexes mate with multiple partners, often in overlapping series just minutes apart<sup>12</sup>, and females frequently carry multiple-paternity litters in the wild<sup>13</sup>. By contrast, its sister species, the old-field mouse, *P. polionotus*, is strictly monogamous as established from both behavioural<sup>14</sup> and genetic data<sup>15</sup>. Moreover, relative testis size is roughly three times larger in *P. maniculatus* than in *P. polionotus*<sup>11</sup>, consistent with the well-documented relationship between relative testis size and level of sperm competition in rodents<sup>16</sup>. Therefore the competitive environments experienced by sperm of *P. maniculatus* and *P. polionotus* males represent divergent selective regimes.

The factors that regulate mammalian reproductive success are numerous and complex, yet when sperm from multiple males compete for a limited number of ova, the quality of each male's sperm can influence who will sire offspring<sup>3</sup>. Under intense competition, sperm motility can be a critical determinant of success<sup>17</sup>. Previous studies have shown that *P. maniculatus* sperm swim with greater velocity than *P. polionotus*<sup>9</sup>. A primary energy source for motility is acquired by oxidative phosphorylation in the mitochondria, which are located within the sperm midpiece<sup>18</sup>. The size of the midpiece is thus predicted to positively influence flagellar thrust and sperm velocity<sup>19</sup> and, indeed, evidence across multiple taxa support the relationship between midpiece size and speed<sup>20–22</sup>.

In this study, we examine the relationship between sperm midpiece length, swimming performance and reproductive success in *P. maniculatus*, *P. polionotus*, and a hybrid population. We then identify a single gene of large effect that regulates the phenotypic difference in sperm midpiece length between the two focal species, and show how allelic variation at this locus influences sperm swimming velocity and ultimately, male fertility.

## Results

**Sperm morphology and performance.** We first measured four sperm traits of mice taken from our laboratory colonies of the two focal species, *P. maniculatus* and *P. polionotus* (Fig. 1a). We found that sperm head size does not differ between these species (Fig. 1b,c), but *P. maniculatus* sperm have longer flagella than *P. polionotus* (Fig. 1d; *t*-test:  $P = 8 \times 10^{-11}$ ,  $df = 9$ ,  $n = 10$  sperm/male). More specifically, the midpiece region of the flagellum is significantly longer in *P. maniculatus* sperm than in *P. polionotus* (Fig. 1e; *t*-test:  $P = 3 \times 10^{-7}$ ,  $df = 9$ ,  $n = 10$  sperm/male). These data are consistent with morphological differences in sperm from wild-caught *P. maniculatus* and *P. polionotus*<sup>10</sup>.

Indeed, sperm from the promiscuous *P. maniculatus* males swim with greater velocity (straight-line velocity [VSL]) than sperm of the monogamous *P. polionotus* (*t*-test:  $P = 0.017$ ,  $df = 8$ ,  $n = 76–549$  sperm/male), consistent with our previous results<sup>9</sup>. Two other means of measuring sperm swimming performance,

**Figure 1 | *Peromyscus* sperm morphology.** (a) Scanning electron micrographs of a mature *P. maniculatus* sperm cell with morphological features labelled. Mean  $\pm$  s.e. of *P. maniculatus* and *P. polionotus* sperm (b) head length, (c) head width, (d) total flagellum length and (e) midpiece length ( $n = 10$  males;  $n = 10$  sperm/male; *t*-test). Sperm head and width do not differ significantly, yet *P. maniculatus* total flagellum and midpiece length are significantly longer than those in *P. polionotus* sperm. Note truncated y axes. NS = *P* value  $> 0.05$ .

curvilinear velocity (VCL; *t*-test:  $P = 0.0024$ ,  $df = 8$ ,  $n = 76–549$  sperm/male) and average path velocity (AVP; *t*-test:  $P = 0.0039$ ,  $df = 8$ ,  $n = 76–549$  sperm/male), showed a similar difference as in the VSL results. Since all three velocity measures were consistent and are non-independent measurements, we focused on the most conservative estimate, VSL, in subsequent analyses (Supplementary Fig. 1).

To assay the relationship between *Peromyscus* midpiece length and swimming performance in a competitive context, we next conducted a series of swim-up assays, a clinical technique used to screen for highly motile spermatozoa that are most likely to achieve fertilization<sup>23</sup>. We tested sperm with variable midpiece lengths by centrifuging cells and collecting sperm best able to swim towards the surface through a viscous media. We first competed sperm from two heterospecific males (*P. maniculatus* versus *P. polionotus*), which as a single mixed sample offers the greatest range of sperm morphology, and found that the most motile sperm had a significantly longer midpiece (Fig. 2; *t*-test:  $P = 3.28 \times 10^{-4}$ ,  $df = 11$ ;  $n = 20$  sperm/trial). We found a strikingly similar result when the competitions involved sperm

**Figure 2 | Competitive sperm swim-up assays.** Mean  $\pm$  s.e. of sperm collected prior to spinning (pre-spin; light grey bars) and from the centrifuged sample surface (post-spin; dark grey bars) in heterospecific (*P. maniculatus* versus *P. polionotus*;  $n = 12$  trials), conspecific (*P. maniculatus* versus *P. maniculatus*;  $n = 15$  trials), and within-male (*P. maniculatus*;  $n = 19$  trials) competitive swim-up assays. In all three assays, the mean midpiece length ( $n = 20$  sperm/sample) of competitive sperm collected following centrifugation was significantly longer than those entering ( $t$ -test). Note truncated y axis.

from two unrelated conspecific males (*P. maniculatus* versus *P. maniculatus*), representing a more biologically relevant competition (Fig. 2;  $t$ -test:  $P = 0.001$ ,  $df = 14$ ;  $n = 20$  sperm/trial), and even within-male competitions (*P. maniculatus*) in which all sperm were harvested from a single male for each trial but still showed variation in midpiece length (Fig. 2;  $t$ -test:  $P = 0.014$ ,  $df = 18$ ;  $n = 20$  sperm/trial). In total, these results suggest that sperm with larger midpiece regions are more motile, and thus more likely to achieve fertilization<sup>16,23</sup>, whether they are competing against heterospecific, conspecific or even of other sperm produced by the same male.

**Genetic mapping of sperm midpiece length.** Next, to dissect the genetic basis of adaptive differences in sperm morphology, we performed a genetic intercross between *P. maniculatus* and *P. polionotus* to produce 300 second-generation hybrid ( $F_2$ ) male offspring. We then genotyped each  $F_2$  male at 504 anonymous loci throughout the genome. We identified a single chromosomal region significantly associated with midpiece length variation on linkage group 4 (LG4; Fig. 3; on the basis of logarithm of odds [LOD], significance determined by a genome-wide permutation test with  $\alpha = 0.01$ ). This single region of the genome explains 33% of sperm midpiece length variation in the  $F_2$  hybrids, and largely

**Figure 3 | Genetic mapping of sperm morphology.** Association between genome-wide SNP markers and total sperm flagellum length (black) and midpiece length (red). Genome-wide significant LOD thresholds for each trait (from 10,000 permutations;  $\alpha = 0.01$ ) indicated by dashed lines. A zoomed in view of Linkage Group 4 (LG4) shows confidence thresholds for QTL associated with midpiece length; 1.5 LOD support interval is shown in orange, the 99% Bayes credible interval is shown; position of the most highly associated gene, *Prkar1a*, is given.  $F_2$  hybrids with recombination events within the 1.5-LOD support threshold ( $n = 11$ ) were used for breakpoint analysis.

recapitulates differences in midpiece length observed between the pure species (Fig. 4). Furthermore, we found that F<sub>2</sub> males carrying at least one *P. maniculatus* allele at this locus have a significantly longer midpiece than those with none (Fig. 4; *t*-test:  $P = 4.44 \times 10^{-15}$ , *df* = 49), suggesting the *P. maniculatus* allele acts in a dominant fashion. Thus, a single large-effect locus explains much of the difference in sperm midpiece length between these two species.

While we found a single significant peak associated with sperm midpiece length on linkage group 4 (Fig. 3), we found no significant quantitative trait loci (QTL) for sperm total flagellum

length (Fig. 3) or any measure of sperm velocity (VSL, VCL, VAP). The lack of significant QTL for total flagellum length or velocity in this cross does not suggest that variation in these traits lack a genetic basis, rather the result may be due to measurement error or an inability to detect genes of small phenotypic effect; due to the complex nature of these traits, it is likely that they are controlled by multiple genes. Moreover, velocity is a composite trait likely influenced by sperm morphology as well as other factors. We performed *post-hoc* scans for each of these phenotypic traits (midpiece, total flagellum, VSL, VCL and VAP with 1,000 permutations,  $\alpha = 0.05$ ) with each other trait, and with the genetic marker of highest linkage, as covariates; we found no additional significant QTL.

To further refine the single QTL for sperm midpiece and identify a causal gene, we enriched marker coverage in the 20 cM region surrounding the marker of highest association by genotyping each F<sub>2</sub> male for eight additional single nucleotide polymorphisms (SNPs; Supplementary Table 1). The increased marker density improved our QTL signal and reduced the 1.5-LOD support interval to 3.3 cM and the 99% Bayes credible interval to a single locus containing the *Prkar1a* gene (Fig. 3). We then confirmed this association with a genetic breakpoint analysis that included two additional SNPs flanking the marker of highest association, thereby narrowing the 3.3 cM interval to 0.8 cM around *Prkar1a* (Fig. 5). The *Prkar1a* gene encodes the R1 $\alpha$  regulatory subunit of the Protein Kinase A (PKA) holoenzyme and is the only gene within the broader 3.3 cM confidence interval previously implicated in male fertility, sperm morphology or sperm motility<sup>24,25</sup> (Supplementary Table 2). Therefore, *Prkar1a* represents a strong candidate for further functional analyses.

**The role of *Prkar1a* in *Peromyscus* reproduction.** We found that R1 $\alpha$  is abundant and localized in the sperm midpiece in *Peromyscus* (Fig. 6a, Supplementary Fig. 2; and in contrast to another potential causal gene within the 0.8 cM QTL peak, the predicted gene LOC102911133, which we found localizes to the

**Figure 4 | Variation in sperm midpiece length between *Prkar1a* genotypes in hybrids relative to parental phenotypes.** Mean  $\pm$  s.e. midpiece length (*n* = 10 sperm/male) of sperm harvested from F<sub>2</sub> hybrid offspring (*P. maniculatus* [*n* = 10; indicated as black bar]  $\times$  *P. polionotus* [*n* = 10; white bar], redrawn from Fig. 1e for reference here). AA denotes males homozygous for the *P. maniculatus* allele at the *Prkar1a* locus (*n* = 61), Aa for heterozygous males (*n* = 130), and aa for males homozygous for the *P. polionotus* allele (*n* = 50). Note truncated y axis. NS = *P* value > 0.05, *t*-test.

**Figure 5 | Fine-scale mapping of sperm midpiece length.** F<sub>2</sub> hybrid males (*n* = 11) that showed a recombination event in the 1.5 LOD support interval associated with the midpiece QTL (see Fig. 3); males are sorted by mean midpiece length ( $\mu$ m) shown by grey circles (*n* = 10 males, *n* = 10 sperm/male) from shortest (top) to longest (bottom). Mean  $\pm$  s.e. midpiece length for pure *P. polionotus*, *P. maniculatus* (redrawn from Fig. 1) and F<sub>1</sub> hybrids are shown for reference. Genotypes for each individual at nine markers: Aa denotes heterozygous genotypes for the *P. maniculatus* and *P. polionotus* alleles, 'aa' for homozygous *P. polionotus* alleles. Red box highlights the *Prkar1a* genotype that shows a perfect association with midpiece length variation unlike neighboring loci.

sperm head (Supplementary Note 1; Supplementary Fig. 3), consistent with studies in humans<sup>26</sup> and rats<sup>27</sup>. To confirm the influence of *Prkar1a* on midpiece length, we examined *Mus musculus* C57BL/6 animals with only a single functional copy of the gene (homozygous knockouts are inviable)<sup>28</sup> and found that the midpiece of *Prkar1a*<sup>+/-</sup> males is significantly shorter than wild type brothers (Fig. 6b; *t*-test:  $P = 4.54 \times 10^{-8}$ ,  $df = 7$ ,  $n = 20$  sperm/male). These findings therefore strongly implicate the *Prkar1a* gene as a major determinant of sperm midpiece length differences observed in *Peromyscus*.

We next investigated how the PKA R1 $\alpha$  subunit differed between our two focal species. First, we found no non-synonymous differences between *P. maniculatus* and *P. polionotus* in the coding exons of *Prkar1a* mRNA (1,146 bp), suggesting that both species produce similar R1 $\alpha$  proteins. This protein is expressed throughout male germ cell development<sup>29</sup>. In whole testis samples, we found no significant differential expression of *Prkar1a* mRNA and R1 $\alpha$  protein levels (mRNA: Supplementary Fig. 4, Bayes factor = 0.071, Posterior Probability = 0.008,  $n = 8$  males; protein: Fig. 7; *t*-test:  $P = 0.664$ ,  $n = 5$  males), possibly because testis samples contain cells of multiple developmental stages. However, in mature, fully

developed sperm released from the caudal epididymis, we found *P. polionotus* expresses significantly more R1 $\alpha$  protein than *P. maniculatus* (Fig. 7; *t*-test:  $P = 0.00235$ ,  $n = 6$  males). These data, in combination with the knockout phenotype in *Mus*, suggest that changes in the expression of R1 $\alpha$  can lead to changes in sperm midpiece length.

#### Linking genotype, phenotype and fitness in a hybrid population.

In addition to genetic mapping, our genetically heterogeneous F<sub>2</sub> hybrid population also enables us to test for statistical associations among traits. First, to test the prediction that sperm midpiece length influences swimming performance, we compared the mean straightline velocity (VSL) to both mean midpiece length and flagellum lengths of sperm from F<sub>2</sub> males using a linear regression, with each trait as the independent variable. While we found no significant association with flagellum length [ $R^2 = 0.003$ ,  $P = 0.29$ ,  $df = 232$ ], midpiece and VSL show a significant positive correlation [Fig. 8a;  $R^2 = 0.028$ ,  $P = 0.0057$ ,  $df = 232$ ], which remains significant after considering flagellum length as a covariate [ $R^2 = 0.028$ ,  $P = 0.012$ ,  $df = 232$ , midpiece was the only coefficient with  $P < 0.05$ ]. Moreover, we found no significant association between midpiece length and total flagellum length in F<sub>2</sub> males ( $R^2 = 0.004$ ,  $P = 0.14$ ,  $df = 232$ ), which suggests that these two traits are genetically independent. These results show that VSL is correlated with midpiece length in *Peromyscus*, either because increase in midpiece length leads to

**Figure 6 | PKA R1 $\alpha$  localization and effect on midpiece length.** (a) PKA R1 $\alpha$  localization in mature *P. maniculatus* sperm cell ( $\times 400$ ); immunofluorescence of anti-PKA R1 $\alpha$  (red) and DAPI (blue). (b) Mean  $\pm$  s.e. midpiece length of wild-type *Prkar1a*<sup>+/+</sup> (red) and heterozygous *Prkar1a*<sup>+/-</sup> (pink) *Mus musculus* C57BL/6 sperm (*t*-test:  $n = 8$  males,  $n = 20$  sperm/male). Note truncated y axis.

**Figure 7 | PKA R1 $\alpha$ .** Mean  $\pm$  s.e. PKA R1 $\alpha$  protein expression as measured by percentage of relative abundance (%RA) in testis ( $n = 5$ ) and epididymal sperm ( $n = 6$ ) samples from *P. polionotus* (white bars) and *P. maniculatus* (black bars) males. NS = *P* value > 0.05, *t*-test.

**Figure 8 | Sperm performance and male fertility in F<sub>2</sub> hybrids.** (a) Association between midpiece length and straight-line velocity of F<sub>2</sub> hybrid males (linear regression:  $n = 233$  males,  $n = 10$  sperm/male). For reference, midpiece length of each parental species is plotted as a dashed line. (b) Mean  $\pm$  s.e. sperm midpiece length of F<sub>2</sub> males that did ( $n = 85$ ) and did not ( $n = 173$ ) sire offspring (*t*-test). Note truncated y axis.

increased speed (that is, variation in these two traits share a pleiotropic genetic basis), or less likely, these two traits are influenced independently by tightly linked genes.

We next examined how variation at the *Prkar1a* locus predicts sperm morphology and performance in the F<sub>2</sub> hybrid population. We found that F<sub>2</sub> males carrying at least one *P. maniculatus Prkar1a* allele (AA or Aa, as defined by the *Prkar1a* SNP) produce sperm with significantly longer midpiece, as mentioned earlier (Fig. 4), but their sperm also swim with greater velocity (VSL) than sperm from males homozygous for *P. polionotus Prkar1a* allele (aa; mean VSL ± s.e.: AA = 78.7 ± 1.9 μm/s, Aa = 77.5 ± 1.1 μm/s, aa = 73.1 ± 1.8 μm/s, *t*-test:  $P_{AA-aa} = 0.040$ ,  $P_{Aa-aa} = 0.044$ , *df* = 49). Therefore, *Prkar1a* genotype is associated with both sperm morphology and swimming performance.

Finally, to understand how allelic and phenotypic variation influences male reproductive success, we scored which F<sub>2</sub> males sired offspring in natural matings. We found that F<sub>2</sub> hybrid males carrying at least one dominant *P. maniculatus Prkar1a* allele were more likely to sire offspring when paired with a female for 2 weeks than those homozygous for the *Prkar1a* ( $\chi^2_{AA-Aa-aa} = 6.35$ ,  $P = 0.042$ , *df* = 2). This is a conservative estimate of male fertility because many false negatives were likely included due to pairs that failed to mate, infanticide, female infertility and other unrelated physiological or behavioural conditions of the animals, which make an effect more difficult to detect. Moreover, this result is consistent with lower reproductive success in pure *P. polionotus* matings compared to *P. maniculatus* under similar conditions ( $z = 1.37$ ,  $P = 0.0071$ , *df* = 19). Furthermore, F<sub>2</sub> males who sired pups had sperm with significantly longer midpiece regions than those that did not reproduce (Fig. 8b; *t*-test:  $P = 0.041$ , *df* = 84). Together, these analyses show that males carrying at least one copy of the *P. maniculatus Prkar1a* allele produce significantly faster sperm with longer midpieces, and also benefit from greater reproductive success, suggesting a direct link between fitness, phenotype and genetic variation at the *Prkar1a* locus.

## Discussion

When females mate with multiple partners within a reproductive cycle, males can continue to compete for reproductive success long after mating has occurred as their sperm compete for the fertilization of a limited number of ova. The strength of post-copulatory sexual selection is therefore largely determined by female mating strategy. In this study, we examined two species of *Peromyscus* mice with divergent mating systems. Female *P. maniculatus* mate with multiple males in a reproductive cycle, allowing for sperm of different males to compete within the female reproductive tract for fertilization success; in contrast, *P. polionotus* females mate monogamously and thus sperm competition is limited. Theory predicts that these differing competitive regimes may favour the evolution of trait divergence. Our results suggest that the difference observed in sperm midpiece length between *P. maniculatus* and *P. polionotus* confers an important reproductive advantage that improves sperm swimming performance. We first found that sperm with longer midpiece are more motile in a competitive swim-up assay. Second, within our hybrid population, we observed a positive relationship among sperm midpiece length, swimming velocity and male reproductive success. The targets of post-copulatory sexual selection can vary tremendously across taxa, but in this system, our results are consistent with the hypothesis that selection favours sperm with longer midpiece regions, consistent with findings in other species<sup>20–22</sup>.

If a simple relationship between midpiece length and fitness exists, it is puzzling why a monogamous species would not share

the same sperm morphology as its promiscuous sister-species. The functional relevance of the midpiece, in both evolutionary and human fertility studies, is controversial<sup>30,31</sup>, and many closely related species vary extensively in this trait<sup>32–34</sup>. Nonetheless, while drift and/or selection acting on pleiotropic traits could lead to shorter midpiece, sperm cells with more or larger mitochondria afforded by the larger midpiece also may experience greater oxidative stress, which is known to increase mutagenesis in germ cells<sup>35</sup>. Therefore, when sperm competition is absent, such as in *P. polionotus*, the benefits conferred by producing faster sperm may not outweigh the associated costs. However, in the highly competitive environment that *P. maniculatus* sperm experience, even small increases in sperm performance could differentiate those that reproduce and those that do not<sup>7</sup>. Thus, the balance between negative and positive effects of cellular respiration in sperm may determine the relative roles of natural and sexual selection as drivers of interspecific midpiece variation seen in *Peromyscus*, and across animals more generally.

Using a forward-genetics approach, we identified a single gene of large effect on midpiece size, *Prkar1a*, which encodes for the R1 $\alpha$  regulatory subunit of the PKA. We then corroborated the role of this gene by demonstrating that lab mice with a dominant negative mutation in *Prkar1a* have shorter midpiece than their wild-type brothers. Successful fertilization requires precise temporal and spatial regulation of PKA activity, the main downstream effector of cellular cyclic AMP concentrations, and is in part, regulated by R1 $\alpha$ <sup>29</sup>. The R1 $\alpha$  subunit is known to influence gross sperm morphology, motility and fertility in humans presenting Carney Complex (a disease associated with mutations in *Prkar1a*) and in *Mus musculus Prkar1a* mutants<sup>24</sup>. While most reports on *Prkar1a* implicate negative consequences for male fertility and are associated with large-scale changes in R1 $\alpha$  expression<sup>24,29,36–38</sup>, our results suggest that the subtle tuning of the expression of this regulatory subunit may also confer beneficial effects. In *Peromyscus*, we found that R1 $\alpha$  is similarly abundant in the testis of the two focal species, yet is differentially expressed in mature sperm of *P. maniculatus* and *P. polionotus*. Considering that the heterogeneous nature of testis tissue contains germ cells at various stages of their differentiation process and Sertoli cells, it is likely that subtle difference in *Prkar1a* mRNA abundance or R1 $\alpha$  protein may not be detectable if expressed in a limited number of cell types. Our analysis of mature spermatozoa, however, suggests that cell type-specific R1 $\alpha$  expression differences present during later stages of *Peromyscus* spermatogenesis are likely to regulate midpiece length.

The rapid evolution of reproductive protein coding regions is a well-known response to post-copulatory sexual selection<sup>39</sup>; we demonstrate here that expression changes in gametes of a broadly expressed gene can also be a target of selection. Over 50% of mammalian genes are expressed in the testis and most of these genes are also expressed in other tissues<sup>5,6</sup>; therefore, cell type-specific changes in protein expression in reproductive tissues are likely to be a common mechanism by which selection in males can operate with swiftness and without deleterious effects in females or other tissues.

## Methods

**Mice.** Wild derived *Peromyscus maniculatus bairdii* and *Peromyscus polionotus subgriseus* were originally obtained from the *Peromyscus* Genetic Stock Center at the University of South Carolina and have been maintained at Harvard University in accordance with guidelines established by Harvard's Institutional Animal Care and Use Committee. Adult sexually mature *P. polionotus* and *P. maniculatus* males were used to collect data for cross-species comparisons. In addition, we bred four mice, two *P. polionotus* males and two *P. maniculatus* females, to produce 40 first-generation (F<sub>1</sub>) hybrids, and then intercrossed siblings to generate second-generation (F<sub>2</sub>) hybrid progeny. For genetic mapping, we used 300 F<sub>2</sub> hybrid males

and obtained genotypic and phenotypic data as described below. All males were sexually mature and were paired with a female prior to harvesting sperm.

*Mus musculus* females heterozygous for the *Prkar1a* locus on a C57BL/6 background<sup>28</sup> were mated to wild type C57BL/6 males to produce wild type and *Prkar1a*<sup>+/-</sup> offspring. These mice were a generous gift of Dr Stanley McKnight at the University of Washington.

**Sperm analysis.** After sacrifice via carbon dioxide overdose, we immediately removed the left caudal epididymis of each F<sub>2</sub> male with a single cut at the intersection of the epididymis and the vas deferens. We then submersed the tissue in 1 ml of warmed Biggers-Whitten-Whittingham (BWW) medium<sup>40</sup>, and incubated the tissue for 10 min at 37 °C to release motile sperm. We then removed the epididymal tissue, gently swirled the solution, placed 20 µl of medium containing live sperm on a plastic microscope slide and covered the sample with a plastic coverslip (plastic reduces adhesion of sperm to the slide compared with glass products). We recorded 5 s videos of live sperm at ×100 magnification under phase contrast conditions on an upright microscope (AxioImager.A1, Zeiss, Jena, Germany). We then acquired sperm swimming performance data from the videos using the Computer Assisted Sperm Analyzer plugin for NIH Image<sup>41</sup> by measuring each motile cell in the frame ( $n = 4\text{--}549$  cells/male) to calculate the mean straight-line velocity (VSL), curvilinear velocity (VCL) and average path velocity (VAP). Cells aggregated into groups, dead sperm cells and those with a beating flagellum but stuck to the slide were excluded from the analysis. Sperm collected from *P. maniculatus* achieved higher velocity than *P. polionotus* sperm on all three measures (Supplementary Fig. 1;  $t$ -test:  $P_{VSL} = 0.017$ ,  $P_{VCL} = 0.0024$ ,  $P_{VAP} = 0.0039$ ,  $n_{\text{male}} = 9$ ).

We preserved the remaining sperm cells in 2% paraformaldehyde (Sigma-Aldrich) for morphological analysis. Following fixation, we spread 20 µl of suspended sperm on a glass microscope slide and mounted the cells in Fluoromount-G (Southern Biotech). We imaged 10 sperms showing no obvious abnormalities from each male at ×400 magnification under phase contrast conditions on an upright microscope (AxioImager.A1), consistent with standard practice<sup>34,42–44</sup>. For each sperm cell from *P. maniculatus* and *P. polionotus* males we measured (1) sperm head length (the longest region of the sperm head), (2) sperm head width (the widest region of the head perpendicular to the length measure), (3) total sperm flagellum length (including midpiece, principal piece and terminal piece of cell), and (4) midpiece length (from the base of the sperm head to the midpiece-principal piece boundary; see Fig. 1a) using the curve-spline tool in the AxioVision Image Analysis Software (Zeiss). Intraclass correlation coefficients among sperm within F<sub>2</sub> hybrid males were significant and high (midpiece = 0.651,  $P < 0.05$ ; flagellum = 0.612,  $P < 0.05$ ), suggesting repeatability of the measure and substantial heritability of sperm morphology, as expected from the significant differences in parental species means. *Mus musculus* C57BL/6 wild type and *Prkar1a*<sup>+/-</sup> males' sperm midpiece regions were measured and analysed identically to *Peromyscus* sperm.

We compared the sample means of pure *P. maniculatus* and *P. polionotus* sperm morphology (head length, head width, total flagellum length, midpiece length) and velocity (VSL, VCL, VAP) using two-tailed unpaired  $t$ -tests and adjusted alpha for multiple comparisons using Bonferroni correction.

F<sub>2</sub> hybrid males that did not produce any sperm were excluded from all analyses incorporating sperm velocity or morphology measures, including genetic mapping; however, we used the genotypic information from these males in linkage map construction (see below). All analyses were performed in R statistical software<sup>45</sup>.

**Fitness assays.** We tested for an effect of sperm midpiece length on competitive success by performing three types of sperm swim-up assay: heterospecific competitions including the sperm of a *P. maniculatus* and a *P. polionotus* male, conspecific competitions between the sperm of two *P. maniculatus* males, and within-male competitions between the sperm of a *P. maniculatus*, including replicates of each assay. We collected live sperm (following methods above) and placed approximately equal concentrations from the two donors (for within-male assays, we added twice the volume of a similar concentration) in 0.5 ml 10% polyvinylpyrrolidone in BWW medium. We took a sample of the sperm mixture ('pre-spin') and centrifuged the mixture at 150 g for 10 min at 37 °C to pellet cells. We then collected a sample of cells just below the surface of the medium following centrifugation ('post-spin') and measured midpiece length of sperm in each sample ( $n = 20$  sperm/sample). The cells near the top of the tube after spinning are those that are capable of rapidly swimming up through a viscous media. To analyse the results from these assays, we used two-tailed paired  $t$ -tests with Bonferroni correction to compare the mean midpiece size of a sample of sperm that entered the competition (the pre-spin sample) to the sperm that were able to swim to the top of the tube after centrifugation (the post-spin sample). This technique is commonly used to screen for the highly motile sperm most likely to achieve fertilization<sup>23,46</sup>.

To test for an effect of sperm morphology on reproductive success (Supplementary Note 1) we weaned each of the F<sub>2</sub> hybrid males from their parents at 25 days of age and housed them with same-sex littermates until they were at least 68 days old and sexually mature. We then housed each male with an F<sub>2</sub> female chosen at random from the same grandparents as the male for at least 7 days (range 7–22 days; we found no effect of pairing length on reproductive success:

unpaired two-tailed  $t$ -test comparing pairing length of sires and non-sires,  $P = 0.34$ ,  $df = 84$ ). This time the male spent paired with a female reduced male phenotypic variability that might arise from dominance hierarchies among male littermates to minimize the differences in reproductive condition among males by exposing all to a female in the oestrus (*Peromyscus* estrous cycle is 5 days<sup>47</sup>). Finally, we sacrificed males at 80–169 days of age to harvest sperm (we found no effect of male age on reproductive success: unpaired two-tailed  $t$ -test comparing mean age of sires and non-sires,  $P = 0.69$ ,  $df = 84$ ), and recorded any observed offspring that resulted from the pairing of these F<sub>2</sub> males with F<sub>2</sub> females.

**Genetic analysis.** We extracted genomic DNA from liver tissue using either phenol chloroform (Automated DNA Extraction Kit, AutoGen) or DNeasy Kits (Blood & Tissue Kit, Qiagen). We identified SNPs and assigned genotypes for each individual by double digest Restriction-site Associated DNA Sequencing (ddRADseq)<sup>48</sup>. Briefly, we digested ~1 µg of gDNA for each individual with two restriction endonucleases: EcoRI and MspI (New England BioLabs, Ipswich). We ligated the resulting fragments to sequencing adapters containing a unique barcode for each individual male. We then pooled these barcoded fragments from multiple individuals and isolated the fragments in the size range of 280–320 bp using a Pippin Prep (Sage BioSciences). Finally, we amplified the remaining fragments using a Phusion High Fidelity PCR Kit (Thermo-Fisher) and sequenced the resulting libraries on a Genome Analyzer Iix or a HiSeq 2500 (Illumina). We recovered 1,753 informative SNP markers that consistently differed between the two parental strains used to generate the hybrid population, and which were confirmed as heterozygous in the first generation hybrids (F<sub>1</sub>). We then pruned our marker set to exclude any markers genotyped in fewer than 100 individuals or with genotype information identical to another marker.

We conducted all genetic mapping analyses using R/qtl software<sup>49</sup>, an add-on package for R statistical software<sup>45</sup>. To construct a genetic linkage map, we calculated linkage distances based on the fraction of recombination events and Logarithm of Odds (LOD) scores between all SNP marker pairs. Next, we grouped markers by varying the recombination parameters until we recovered a map with 23 linkage groups containing at least five markers each (the karyotypes of both species are known [ $n = 24$  chromosomes]); however, we are unable to recover the majority of the Y chromosome with the cross design employed in this study. Any markers not included in the 23 linkage groups were excluded. Finally, we refined this map by ordering the markers within each linkage group in overlapping windows of eight markers and minimizing the frequency of recombination events between markers in each window. The resulting genetic linkage map contained 504 in 23 linkage groups.

To identify QTL contributing to sperm morphology, we performed Haley-Knott regression and interval mapping analyses sequentially with 1,000 permutations and  $\alpha = 0.05$  in R/qtl<sup>49</sup>. We found a single genomic region with a significant association for sperm midpiece length on LG4 (Fig. 3); LG4 is syntenic to *Mus musculus* chromosome 11 and *Rattus norvegicus* chromosome 10<sup>50</sup>. To narrow the QTL interval, we genotyped the F<sub>2</sub> males for additional markers within the 20 cM region of the genome surrounding the marker most strongly associated with sperm midpiece length (Supplementary Table 1; Supplementary Note 1). This region of interest is syntenic to chromosome 11:97–114 Mb in *M. musculus* and chromosome 10:91–104 Mb in *R. norvegicus*<sup>51</sup>. We designed markers in eight genes—*Foxj1*, *Kcnj16*, *Prkar1a*, *Prkca*, *Fmnl1*, *Klh10*, *Slc25a39* and *Tll6*—based on position and prioritized those implicated in male fertility, spermatogenesis, cytoskeletal organization, mitochondrial function, and/or specifically or highly expressed in the testis or during spermatogenesis<sup>51–53</sup>. We genotyped all F<sub>2</sub> males for informative SNPs residing in each of these genes using custom designed TaqMan SNP Genotyping Assays (Thermo-Fisher), except in the case of *Tll6*, where we used a restriction enzyme digest assay (all primers and TaqMan probe sequences are available in Supplementary Table 1; methods followed manufacturer's instructions). The genotype data from these eight SNP markers helped to better refine the QTL for sperm midpiece length and increased the association between genotype and phenotype (peak LOD score = 25.7 [genome-wide LOD threshold = 3.69 with 10,000 permutations and  $\alpha = 0.01$ ]). Using two measures of confidence, we found that midpiece length mapped to (1) a single marker residing in the gene, *Prkar1a*, based on the 99% Bayes credible interval, and (2) to a 3.3 cM region surrounding *Prkar1a* based on 1.5 LOD support interval<sup>49</sup>. We then PCR-amplified (primers available in Supplementary Table 1) and sequenced ~1 kb of gDNA fragments within the genes *Abca8a* and *Amz2* in the parents of the cross and all F<sub>2</sub> males that showed a recombination event in the surrounding region ( $n = 13$ ; Fig. 5). On the basis of midpiece length of these F<sub>2</sub> recombinants and their genotypes at the two additional markers, we were further able to narrow the QTL to 0.8 cM by excluding association with *Amz2* and *Abca8a* (Fig. 5) and confirm the association between midpiece length and *Prkar1a*.

To investigate the association between reproductive success and genotype, we compared the frequencies of F<sub>2</sub> males homozygous for the *P. maniculatus* *Prkar1a* allele (AA), the *P. polionotus* allele (aa), or heterozygous (Aa) who sired offspring using a  $3 \times 2$  Chi-squared contingency table ( $\chi^2_{AA-Aa-aa} = 6.35$ ,  $P = 0.042$ ,  $df = 2$ ).

To investigate genetic differences between *P. maniculatus* and *P. polionotus* within *Prkar1a*, we sequenced the protein-coding region by extracting mRNA from the decapsulated testis tissue of *P. maniculatus* and *P. polionotus* males using an RNeasy Mini Kit (Qiagen), converting the mRNA to cDNA using SuperScript II

Reverse Transcriptase (Thermo-Fisher) and a poly-T primer (T16). We amplified the entire coding sequence (1,146 bp) using two pairs of primers (named by location in *Prkar1a*): Exon1c\_F: 5'GCCATGGTTCCTCTGTCTG3', Exon8\_R: 5'AGAAGCTATCCCTGGCTCT3'; Exon7\_F: 5'ATGTGAAACTGTGGG GCATT3' and 3'UTR\_R: 5'ACGACCCAGTACTTGCCATC3'.

To estimate *Prkar1a* mRNA abundance in whole testis of *P. maniculatus* and *P. polionotus* ( $n = 8$ ), we conducted an RNAseq experiment. Specifically, we extracted total RNA using the TRIzol reagent (Thermo-Fisher), purified it with RNeasy Mini Kit (Qiagen), and constructed cDNA libraries using the TruSeq RNA v2 Kit (Illumina) following manufacturer instructions. Multiplexed libraries were sequenced on an Illumina HiSeq2500 (Illumina) in paired-end mode with a read length of 150 bp (average read depth = 30.4 million reads/sample). We removed low quality and adaptor bases from raw reads using TrimGalore v0.4.0 ([http://www.bioinformatics.babraham.ac.uk/projects/trim\\_galore/](http://www.bioinformatics.babraham.ac.uk/projects/trim_galore/)) and mapped the trimmed reads to the genome using the STAR RNA-Seq aligner v2.4.2a in two-pass mode<sup>54</sup>. We next obtained the *P. maniculatus* genome sequence and annotation from the Peromyscus Genome Project (Baylor College of Medicine; <https://www.hgsc.bcm.edu/peromyscus-genome-project>) and created a *P. polionotus* genome and annotation by incorporating SNPs and indels into the *P. maniculatus* Pman\_1.0 reference (GCA\_000500345.1). We estimated expression using STAR alignments in transcriptomic coordinates and the MMSEQ package v1.0.8<sup>55</sup>, and calculated differential expression using MMDIFF<sup>56</sup>.

To validate the *Prkar1a* mRNA estimates from RNAseq, we conducted quantitative PCR on testis of *P. maniculatus* and *P. polionotus*. First, we extracted mRNA from whole testis using an RNeasy Mini Kit, converted the mRNA to cDNA with SuperScript II Reverse Transcriptase (Thermo-Fisher) using a poly-T primer (T16). We then amplified a fragment with identical primer-binding sites *P. maniculatus* and *P. polionotus* using KAPA SYBR FAST Universal 2X qPCR Master Mix (Kapa Biosystems) and the following primers: 5'TCCAGAAG CACAACATCCAG3' and 5'TTCATCTCCCTGGAGTCAG3'. We conducted assays in triplicate, calculated  $\Delta CT$  values with TATA Binding Protein (*TBP*; 5'CTCCCTTGTACCCTTCACCA3' and 5'GAAGCGCAATGGT CTTTAGG3'), a standard control gene and validated with RNAseq. To test for significant differences in RNA abundance, between *P. maniculatus* and *P. polionotus* males, we used two-tailed unpaired *t*-tests.

**Protein analysis.** To localize the expression of PKA R1 $\alpha$ , we fixed epididymal sperm in 2% paraformaldehyde and 1.25% glutaraldehyde on a microscope slide for 15 min. We then washed the cells in phosphate-buffered saline with 0.1% Tween 20 (PBT) for 15 min, and blocked in PBT with 3% bovine serum albumin (BSA) for 1 h at room temperature (RT). Next we incubated the cells overnight at 4°C with the primary antibody, PKA R1 $\alpha$  (Santa Cruz Biotechnology #18800), which we diluted 1:100 in PBT with 3% BSA. The following day we washed cells in PBT for 1 h at RT three times, then incubated with the secondary antibody, Alexa Fluor 546 (Thermo-Fisher #A11056), diluted 1:500 in PBT with 3% BSA, at 1:1,000 for 1 h at RT. Cells were then washed in PBT for 1 h at RT three times, stained with DAPI (Thermo-Fisher) to visualize DNA within cells for 15 min at RT, washed a final time in PBT for 15 min, and mounted in Fluoromount-G (Southern Biotech). In addition, we controlled for non-specific binding of the secondary antibody by performing a side-by-side comparison with cells processed identically to the above methods except that instead of treating with the primary antibody, cells were solely treated with PBT with 3% BSA, the secondary antibody and DAPI. We viewed cells at  $\times 400$  and  $\times 1000$  magnification on an upright microscope (AxioImager.A1, Zeiss).

After sacrifice via carbon dioxide overdose, we removed one testis and stored one at  $-80^{\circ}\text{C}$ , and submersed both caudal epididymes in 1 ml of Modified Sperm Washing Medium (Irvine Scientific) at  $37^{\circ}\text{C}$  for 10 min to release motile sperm. We then removed the epididymes and incubated sperm for an additional 45 min at  $37^{\circ}\text{C}$  before pelleting them at 12,000 g for 5 min. We washed sperm cells in phosphate buffered saline twice, and stored the sample at  $-80^{\circ}\text{C}$ . We lysed samples at 50 Hz for 2 min in lysis buffer (8 M Urea, 1% SDS, 50 mM Tris pH 8.5, cOmplete Protease Inhibitor [Roche], PhosSTOP [Roche]), rocked for 30 min and centrifuged 12,000 g for 20 min, all at  $4^{\circ}\text{C}$ . Samples were then processed for multiplexed quantitative mass spectrometry analysis and analysed through the Thermo Fisher Scientific Center for Multiplexed Proteomics at Harvard Medical School. Samples were subjected to tandem protein digestion using trypsin and Lys-C protease (Thermo-Fisher), peptide labelling with Tandem Mass Tag (TMT) 10-plex reagents and peptide fractionation into 12 fractions. Multiplexed quantitative mass spectrometry data were collected on an Orbitrap Fusion mass spectrometer operating in an MS3 mode using synchronous precursor selection for the MS2 – MS3 fragmentation<sup>57</sup>. MS/MS data were searched with SEQUEST against a custom *Peromyscus* database with both the forward and reverse sequences, and included controlling peptide and protein level false discovery rates, assembling proteins from peptides, and protein quantification from peptides. We compared the relative abundance PKA R1 $\alpha$ , normalized across all TMT reporter channels, in *P. maniculatus* and *P. polionotus* sperm and testis using two-tailed unpaired *t*-tests.

**Data availability statement.** The authors declare that all data supporting the findings of this study are available within the article and its Supplementary Information files or from the corresponding author upon reasonable request. Sequence data from this study have been deposited in GenBank under the

accession codes KF005595 and KF005596. RNAseq data have been deposited in the GenBank/EMBL/DBJ Sequence Read Archive under the accession code PRJ NA343919.
